

# **L6b:** Single Index Models, Portfolio Allocation, and a Risk-Free Asset

---

CHEME 5660 Cornell University

# Disclaimer and Risks

**Training only.** This content is for training and informational purposes only. The teaching team does not make, give, or endorse any offer or solicitation to buy or sell securities or derivative products, or provide investment or trading advice or strategy.

**Risk.** Trading involves risk and is generally not recommended for those with limited resources, experience, or a low risk tolerance. Past performance does not guarantee future success.

**Responsibility.** You are responsible for your investment decisions based on your financial circumstances, objectives, risk tolerance, and liquidity needs.

# Objectives for Today

By the end of this lecture, you should be able to:

- **Interpret and estimate a single index model (SIM):** explain how a factor model describes co-movement, interpret alpha, beta, and the residual, and estimate the parameters, their uncertainty, and the fit.
- **Build minimum-variance portfolios from SIM inputs:** derive the SIM mean vector and covariance matrix, identify the co-movement the model leaves out, and compare the allocations with data-driven portfolios.
- **Add a risk-free asset:** derive the capital allocation line, compute the tangent portfolio, and explain how lending, borrowing, and financing limits affect portfolio choice.

# Lectures and Examples

**Lecture:** Single Index Models, Portfolio Allocation, and a Risk-Free Asset

**Example 1:** Estimate Single Index Models from Historical Data

Fit one firm, then every firm in the dataset, and save the portfolio inputs.

**Example 2:** Estimate Parameter Uncertainty by Simulation

Compare the classical confidence intervals with 1,000 bootstrap estimates.

**Example 3:** Compare Data-Driven and SIM Portfolios

Compare the inputs, frontiers, holdings, and 2025 performance of both portfolios.

**Example 4:** Construct the Tangent Portfolio and Capital Allocation Line

Find the tangent portfolio and compare complete portfolios that lend or borrow.

# Company Profile: MSCI

MSCI, originally Morgan Stanley Capital International, builds the indexes, risk models, and data that investors use to measure markets and manage portfolio risk. In 2004 it combined with Barra, the risk-modeling firm Barr Rosenberg founded in 1975.

- **Indexes:** the [MSCI ACWI](#) covers about 85% of the investable stock market in 47 countries. Investors use indexes like this as the market when they measure beta.
- **Factor risk models:** the [Barra models](#) describe how more than 90,000 securities move together using market, country, industry, and style factors.
- **Predicting beta:** [Rosenberg and Guy \(1976\)](#) showed that a firm's business fundamentals help predict its beta.

Today's connection: the SIM is the simplest factor model. What does one market factor leave out?

---

**Explore:** [Early careers](#)   [Factor Modeling \(MIT OpenCourseWare\)](#)

# Factor Models

The minimum-variance problem of L6a needs a covariance for every pair of assets:  $|\mathcal{P}|(|\mathcal{P}| + 1)/2$  numbers from the same few years of data. Yet most stocks move together when market-wide news arrives. A **factor model** explains that shared movement with a few common factors:

$$g_{i,t} = \underbrace{\alpha_i}_{\text{firm}} + \underbrace{\beta_i g_{M,t}}_{\text{market}} + \underbrace{\sum_{j=1}^m \gamma_{ij} f_{j,t}}_{\text{other factors}} + \underbrace{\varepsilon_{i,t}}_{\text{residual}}$$

where  $g_{i,t}$  and  $g_{M,t}$  are the growth rates ( $\text{year}^{-1}$ ) of asset  $i$  and the market on day  $t$ . The  $f_{j,t}$  are  $m$  other factors, such as interest rates or inflation, and  $\beta_i$  and  $\gamma_{ij}$  are the asset's sensitivities to the factors.

# Two Well-Known Factor Models

In our growth-rate notation:

**Capital Asset Pricing Model (CAPM)**: the market is the only factor, in excess of the risk-free growth rate  $g_f$ , with no intercept:

$$g_{i,t} - g_f = \beta_i (g_{M,t} - g_f) + \varepsilon_{i,t}$$

**Fama–French three-factor model**: size and value factors join the market:

$$g_{i,t} = \alpha_i + \beta_i g_{M,t} + s_i \text{SMB}_t + h_i \text{HML}_t + \varepsilon_{i,t}$$

where  $s_i$  and  $h_i$  are the sensitivities to SMB (small minus big firms) and HML (high minus low book-to-market firms). The three factors explain over 90% of the return variation in 21 of 25 test portfolios, versus 2 for the market alone.

We keep only the market factor: the **single index model (SIM)**.

---

**Source:** Fama and French (1993)

# The Single Index Model

With SPY as the market, for asset  $i \in \mathcal{P}$  on trading day  $t$  (Sharpe, 1963):

$$g_{i,t} = \underbrace{\alpha_i}_{\text{intercept}} + \underbrace{\beta_i g_{M,t}}_{\text{market}} + \underbrace{\varepsilon_{i,t}}_{\text{residual}}$$

Here,  $\beta_i$  is the **market exposure** (dimensionless) and  $\varepsilon_{i,t}$  is the **idiosyncratic** residual. Growth rates,  $\alpha_i$ , and  $\varepsilon_{i,t}$  are in  $\text{year}^{-1}$ . For a single day, the model assumes:

$$\underbrace{\mathbb{E}[\varepsilon_i] = 0}_{\text{zero mean}}$$

$$\underbrace{\text{Cov}(\varepsilon_i, g_M) = 0}_{\text{uncorrelated with the market}}$$

$$\underbrace{\text{Cov}(\varepsilon_i, \varepsilon_j) = 0 \ (i \neq j)}_{\text{uncorrelated across assets}}$$

The first two determine  $\alpha_i$  and  $\beta_i$ . The third, **only the market links two assets**, is an extra assumption that Example 1 checks.

# What Do the Parameters Mean?

Taking the covariance with  $g_M$  and the expectation of both sides of the SIM gives:

$$\text{Cov}(g_i, g_M) = \underbrace{\text{Cov}(\alpha_i, g_M)}_{=0} + \beta_i \underbrace{\text{Cov}(g_M, g_M)}_{=\text{Var}(g_M)} + \underbrace{\text{Cov}(\varepsilon_i, g_M)}_{=0}$$

$$\Rightarrow \beta_i = \boxed{\frac{\text{Cov}(g_i, g_M)}{\text{Var}(g_M)} = \rho_{iM} \frac{\sigma_{g,i}}{\sigma_{g,M}}}$$

$$\alpha_i = \mathbb{E}[g_i] - \beta_i \mathbb{E}[g_M]$$

where  $\sigma_{g,i}$  and  $\sigma_{g,M}$  are growth-rate standard deviations and  $\rho_{iM}$  is their correlation.

**Beta is the slope of the line:** the change in the asset's predicted growth rate per unit change in the market growth rate.

# Systematic and Idiosyncratic Risk

The **risk interpretation** of beta comes from the variance of both sides of the SIM:

$$\text{Var}(g_i) = \beta_i^2 \text{Var}(g_M) + \text{Var}(\varepsilon_i) + 2\beta_i \underbrace{\text{Cov}(g_M, \varepsilon_i)}_{=0} \quad (\alpha_i \text{ is constant})$$

$$= \boxed{\underbrace{\beta_i^2 \sigma_{g,M}^2}_{\text{systematic}} + \underbrace{\sigma_{g,\varepsilon,i}^2}_{\text{idiosyncratic}}}$$

- **Systematic**: comes from the market. Adding assets that share the same market does not diversify it away.
- **Idiosyncratic**: belongs to the asset alone, with residual variance  $\sigma_{g,\varepsilon,i}^2 = \text{Var}(\varepsilon_i)$ .

# Beta as a Measure of Relative Risk

- $\beta_i = 1$ : the asset carries the same systematic risk as the market.
- $\beta_i > 1$ : the asset carries more systematic risk than the market, so its total variance is also larger.
- $0 < \beta_i < 1$ : the asset carries less systematic risk, but its total variance can still be larger when the residual variance dominates.
- $\beta_i < 0$ : the asset moves against the market.

In our dataset, the betas run from near zero to a little above two, with a median close to one.

How do we estimate  $\alpha_i$  and  $\beta_i$  from data?

# Estimating the Parameters

We estimate the SIM one asset at a time by **least squares**, which minimizes the sum of squared residuals over  $N$  trading days:

$$\underbrace{\begin{bmatrix} g_{i,1} \\ \vdots \\ g_{i,N} \end{bmatrix}}_{\mathbf{y}} = \underbrace{\begin{bmatrix} 1 & g_{M,1} \\ \vdots & \vdots \\ 1 & g_{M,N} \end{bmatrix}}_{\hat{\mathbf{X}}} \underbrace{\begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}}_{\boldsymbol{\theta}_i} + \boldsymbol{\varepsilon}, \quad \boxed{\hat{\boldsymbol{\theta}}_i = \arg \min_{\boldsymbol{\theta}} \|\mathbf{y} - \hat{\mathbf{X}}\boldsymbol{\theta}\|_2^2 = (\hat{\mathbf{X}}^\top \hat{\mathbf{X}})^{-1} \hat{\mathbf{X}}^\top \mathbf{y}}$$

The estimates are the sample versions of the parameter formulas,  $\hat{\beta}_i = \widehat{\text{Cov}}(g_i, g_M) / \widehat{\text{Var}}(g_M)$  and  $\hat{\alpha}_i = g'_i - \hat{\beta}_i g'_M$ , with sample means  $g'_i$  and  $g'_M$ . The residuals  $\mathbf{r} = \mathbf{y} - \hat{\mathbf{X}}\hat{\boldsymbol{\theta}}_i$  estimate  $\boldsymbol{\varepsilon}$ .

---

**Example 1:** [Estimate Single Index Models from Historical Data](#)

# Parameter Uncertainty and Goodness of Fit

**How well does the model fit?** The coefficient of determination is the fraction of the asset's growth-rate variation that the market term explains:

$$R^2 = 1 - \frac{\|\mathbf{r}\|_2^2}{\sum_{t=1}^N (g_{i,t} - g'_i)^2}$$

With an intercept,  $R^2$  is the squared sample correlation, an estimate of  $\rho_{iM}^2$ .

**How precise are the estimates?** Assuming the errors are uncorrelated across days with constant variance:

$$s_{g,\varepsilon,i}^2 = \frac{\|\mathbf{r}\|_2^2}{N-2}, \quad \widehat{\text{Cov}}(\hat{\boldsymbol{\theta}}_i) = s_{g,\varepsilon,i}^2 (\hat{\mathbf{X}}^\top \hat{\mathbf{X}})^{-1}$$

The standard errors are the square roots of the diagonal. Each has its parameter's units, and smaller values mean more precise estimates. With thousands of daily observations, a 95% interval is the estimate plus or minus about 1.96 standard errors.

# What If We Had Another Dataset?

The bootstrap answers this by simulation:

**Initialization:** Given  $\hat{\mathbf{X}}$ , the estimates  $\hat{\boldsymbol{\theta}}_i$ , the residuals  $\mathbf{r}$ , and the number of samples  $K$ , fit a normal distribution to the residuals.

For each  $k = 1, 2, \dots, K$  **do**:

1. Draw synthetic residuals  $\boldsymbol{\varepsilon}^{(k)}$  from the fitted normal distribution.
2. Create synthetic observations:  $\mathbf{y}^{(k)} \leftarrow \hat{\mathbf{X}}\hat{\boldsymbol{\theta}}_i + \boldsymbol{\varepsilon}^{(k)}$ .
3. Estimate parameters from them:  $\hat{\boldsymbol{\theta}}^{(k)} \leftarrow (\hat{\mathbf{X}}^\top \hat{\mathbf{X}})^{-1} \hat{\mathbf{X}}^\top \mathbf{y}^{(k)}$ .

Compare the spread of  $\hat{\boldsymbol{\theta}}^{(1)}, \dots, \hat{\boldsymbol{\theta}}^{(K)}$  with the standard errors.

---

**Example 2:** [Estimate Parameter Uncertainty by Simulation](#)

# The Covariance Implied by a SIM

Stacking the SIM gives  $\mathbf{g} = \boldsymbol{\alpha} + \boldsymbol{\beta} g_M + \boldsymbol{\varepsilon}$ . Under the three assumptions:

|                                                                                                                                                   |                        |
|---------------------------------------------------------------------------------------------------------------------------------------------------|------------------------|
| $\mu_g = \boldsymbol{\alpha} + \boldsymbol{\beta} \mu_{g,M}$                                                                                      | mean growth rates      |
| $\Sigma_g = \underbrace{\sigma_{g,M}^2 \boldsymbol{\beta} \boldsymbol{\beta}^\top}_{\text{market}} + \underbrace{\mathbf{D}_g}_{\text{residual}}$ | growth-rate covariance |

where  $\mu_{g,M} = \mathbb{E}[g_M]$ ,  $\sigma_{g,M}^2 = \text{Var}(g_M)$ , and  $\mathbf{D}_g = \text{diag}(\sigma_{g,\varepsilon,1}^2, \dots, \sigma_{g,\varepsilon,|\mathcal{P}|}^2)$ . Off the diagonal,  $\text{Cov}(g_i, g_j) = \beta_i \beta_j \sigma_{g,M}^2$ .

- **Fewer parameters:**  $2|\mathcal{P}| + 1$  numbers instead of  $|\mathcal{P}|(|\mathcal{P}| + 1)/2$ . For the S&P 500, about a thousand instead of more than a hundred thousand.
- **What is assumed away:** covariance between residuals. Most residual correlations are near zero, but some bank pairs exceed 0.6.

# Portfolio Risk under a SIM

For fixed weights  $\mathbf{w}$ , the portfolio growth rate  $g_p = \mathbf{w}^\top \mathbf{g}$  follows a SIM with portfolio beta  $\beta_p = \mathbf{w}^\top \boldsymbol{\beta}$ . Its variance is:

$$\text{Var}(g_p) = \underbrace{\beta_p^2 \sigma_{g,M}^2}_{\text{market risk}} + \underbrace{\sum_{i \in \mathcal{P}} w_i^2 \sigma_{g,\varepsilon,i}^2}_{\text{residual risk}}$$

- **Market risk**: depends on the weights only through  $\beta_p$ . Adding assets with the same market exposure does not reduce it.
- **Residual risk**: with equal weights  $w_i = 1/|\mathcal{P}|$  and every residual variance below  $\bar{\sigma}^2$ , it is at most  $\bar{\sigma}^2/|\mathcal{P}|$ .
- **Diversification**: with uncorrelated residuals, spreading the weights drives residual risk toward zero and leaves the market risk set by  $\beta_p$ .

# Estimated SIM Portfolio Inputs

Substituting the estimates for the population quantities gives the SIM inputs:

$$\hat{\mathbf{g}}_{\text{SIM}} = \hat{\boldsymbol{\alpha}} + \hat{\boldsymbol{\beta}} g'_M, \quad \hat{\boldsymbol{\Sigma}}_{g,\text{SIM}} = s_{g,M}^2 \hat{\boldsymbol{\beta}} \hat{\boldsymbol{\beta}}^\top + \hat{\mathbf{D}}_g$$

where  $g'_M$  and  $s_{g,M}^2$  are the market's sample mean and variance, and  $\hat{\mathbf{D}}_g$  holds the residual variances, all from the training days. Compared with the L6a inputs:

- **The SIM mean vector is the sample-mean vector:** a least-squares line with an intercept passes through the sample means  $\mathbf{g}'$ , so  $\hat{\mathbf{g}}_{\text{SIM}} = \mathbf{g}'$ .
- **The SIM covariance drops the residual covariances:** off the diagonal, the sample covariance  $\hat{\boldsymbol{\Sigma}}_g$  splits as  $\hat{\Sigma}_{g,ij} = \hat{\beta}_i \hat{\beta}_j s_{g,M}^2 + \widehat{\text{Cov}}(\mathbf{r}_i, \mathbf{r}_j)$ , and the SIM keeps the first term. On the diagonal, the two differ only by  $(N-1)/(N-2) \approx 1$  on the residual variance.

Every residual variance is positive, so  $\hat{\boldsymbol{\Sigma}}_{g,\text{SIM}}$  is positive definite and every feasible allocation problem has a unique solution.

# The Long-Only Problem with SIM Inputs

SIM-1 is L6a's long-only problem with SIM inputs and a floor  $g_\star$  (year<sup>-1</sup>):

|                                                                                                                                                                                                                                                                                                                                                                                                                            |                                                                                                                                                                                                                                                   |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\begin{aligned} &\underset{\mathbf{w}}{\text{minimize}} && \underbrace{s_{g,M}^2 (\hat{\boldsymbol{\beta}}^\top \mathbf{w})^2}_{\text{market risk}} + \underbrace{\sum_i s_{g,\varepsilon,i}^2 w_i^2}_{\text{residual risk}} \\ &\text{subject to} && \hat{\mathbf{g}}_{\text{SIM}}^\top \mathbf{w} \geq g_\star \\ & && \mathbf{1}^\top \mathbf{w} = 1 \\ & && 0 \leq w_i \leq 1, \quad i \in \mathcal{P} \end{aligned}$ | $\begin{aligned} &\text{minimize} && \mathbf{w}^\top \hat{\boldsymbol{\Sigma}}_{g,\text{SIM}} \mathbf{w} \\ & && \text{meet or exceed the growth target} \\ & && \text{weights sum to one} \\ & && \text{exclude short positions.} \end{aligned}$ |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

This is L6a's LO-1 with a different covariance and the same means. Sweeping  $g_\star$  up from the long-only GMV growth rate traces the efficient frontier. We compare both allocations under one covariance, then on 2025 prices.

---

**Example 3:** [Compare Data-Driven and SIM Portfolios](#)

# Adding a Risk-Free Asset

A **risk-free asset** has a known growth rate  $g_f$  (year<sup>-1</sup>) and zero variance over the holding period, such as a Treasury bill held to maturity:

- **Capital allocation line (CAL):** mixing the risk-free asset with a risky portfolio gives a straight line from  $(0, g_f)$  through that portfolio.
- **Tangent portfolio  $\mathcal{T}$ :** the steepest such line touches the efficient frontier at  $\mathcal{T}$ .
- **Lending and borrowing:** points before  $\mathcal{T}$  lend at  $g_f$ , and points beyond it borrow at  $g_f$ .

# The Capital Allocation Line

Put a fraction  $w_f$  of wealth in the risk-free asset and  $1 - w_f$  in a risky portfolio  $p$  with  $\sigma_{g,p} > 0$ . The **complete portfolio**  $c$  has:

$$\mathbb{E}[g_c] = g_f + (1 - w_f)(\mathbb{E}[g_p] - g_f), \quad \sigma_{g,c} = |1 - w_f| \sigma_{g,p}$$

For  $w_f \leq 1$ , substituting  $1 - w_f = \sigma_{g,c}/\sigma_{g,p}$  gives the **capital allocation line**:

$$\mathbb{E}[g_c] = g_f + \underbrace{\frac{\mathbb{E}[g_p] - g_f}{\sigma_{g,p}}}_{\text{Sharpe ratio } \text{SR}_p} \sigma_{g,c}$$

We lend for  $0 < w_f < 1$ , hold  $p$  alone for  $w_f = 1$ , and borrow for  $w_f < 0$ . For daily data, the slope is a one-day Sharpe ratio.

---

**Annualized:** Under L5b's model of independent increments,  $\text{SR}_p^{\text{annual}} = \sqrt{\tau/\Delta t} \text{SR}_p \approx 15.9 \text{SR}_p$  for  $\tau = 1$  year and  $\Delta t = 1/252$  years ([Sharpe, 1994](#)).

# The Tangent Portfolio

The **tangent portfolio**  $\mathcal{T}$  maximizes the Sharpe ratio. Let  $\Sigma_g$  be positive definite, let the GMV portfolio's expected growth exceed  $g_f$ , and define  $\mathbf{e} = \boldsymbol{\mu}_g - g_f \mathbf{1}$ . With short positions allowed, solve:

$$\underset{\mathbf{w}}{\text{maximize}} \quad \frac{\mathbf{e}^\top \mathbf{w}}{\sqrt{\mathbf{w}^\top \Sigma_g \mathbf{w}}} \quad \text{subject to} \quad \mathbf{1}^\top \mathbf{w} = 1 \quad (\text{T-1})$$

At a stationary point,  $\Sigma_g \mathbf{w} = (\mathbf{w}^\top \Sigma_g \mathbf{w} / \mathbf{e}^\top \mathbf{w}) \mathbf{e}$ , so the weights point in the direction  $\Sigma_g^{-1} \mathbf{e}$ . Requiring them to sum to one gives:

$$\boxed{\mathbf{w}_{\mathcal{T}} = \frac{\Sigma_g^{-1} (\boldsymbol{\mu}_g - g_f \mathbf{1})}{\mathbf{1}^\top \Sigma_g^{-1} (\boldsymbol{\mu}_g - g_f \mathbf{1})}} \quad (\text{T-3})$$

With long-only weights, there is no closed form, so we solve numerically.

# Two-Fund Separation

The steepest CAL separates choosing a risky portfolio from choosing how much risk to take. Mean-variance investors with the same inputs and risk-free rate hold the **same risky fund**  $\mathcal{T}$ , combined with the risk-free asset. Their risk preferences set  $w_f$  (Tobin, 1958).

Real investors face limits on how they finance their positions:

- **Long-only weights**: the risky fund is the long-only maximum-Sharpe portfolio, and investors still choose  $w_f$ .
- **No borrowing** ( $w_f \geq 0$ ): the efficient boundary follows the CAL up to  $\mathcal{T}$ , then the risky efficient frontier.
- **Costlier borrowing**: a borrowing rate above  $g_f$  gives borrowers a flatter line through a different risky portfolio.

# Risky and Risk-Free Allocation with SIM Inputs

Choose the risky weights  $\mathbf{w}$  and put the rest,  $w_f = 1 - \mathbf{1}^\top \mathbf{w}$ , in the risk-free asset. For a target  $g_\star > g_f$  (year<sup>-1</sup>), problem SIM-2 is:

|                                                                                                                                   |                                  |
|-----------------------------------------------------------------------------------------------------------------------------------|----------------------------------|
| minimize $\mathbf{w}^\top \hat{\Sigma}_{g, \text{SIM}} \mathbf{w}$                                                                | minimize growth-rate variance    |
| subject to $\hat{\mathbf{g}}_{\text{SIM}}^\top \mathbf{w} + \underbrace{(1 - \mathbf{1}^\top \mathbf{w})}_{w_f} g_f \geq g_\star$ | meet or exceed the growth target |
| $0 \leq w_i \leq 1, \quad i \in \mathcal{P}$                                                                                      | exclude short positions.         |

The fraction  $w_f$  has no sign constraint, so  $w_f < 0$  means borrowing at  $g_f$ .

Eliminating  $w_f$  gives the excess-growth constraint  $(\hat{\mathbf{g}}_{\text{SIM}} - g_f \mathbf{1})^\top \mathbf{w} \geq g_\star - g_f$ .

# The Solutions Lie on a Ray

Scaling  $\mathbf{w}$  by  $c > 0$  scales the excess growth by  $c$  and the variance by  $c^2$ . So, until a bound  $w_i \leq 1$  binds, every target selects the same risky direction:

$$\mathbf{w}(g_\star) = (1 - w_f) \mathbf{w}_{\mathcal{T}}, \quad 1 - w_f = \frac{g_\star - g_f}{\hat{\mathbf{g}}_{\text{SIM}}^\top \mathbf{w}_{\mathcal{T}} - g_f} \quad (\text{SIM-3})$$

where the long-only tangent portfolio,  $\mathbf{w}_{\mathcal{T}} = \mathbf{w} / \mathbf{1}^\top \mathbf{w}$ , is any solution rescaled to sum to one.

- Targets below  $\hat{\mathbf{g}}_{\text{SIM}}^\top \mathbf{w}_{\mathcal{T}}$  lend ( $0 < w_f < 1$ ).
- Targets above it borrow ( $w_f < 0$ ).

The estimation-risk notebook asks how much these allocations move when the inputs change.

---

**Example 4:** [Construct the Tangent Portfolio and Capital Allocation Line](#)

# Optional Advanced Material

These notebooks extend today's material. The [advanced index](#) gives a suggested order.

- [SIM estimation theory](#): the ridge estimator, its covariance, and the two bootstraps.
- [Residual diagnostics and two bootstrap methods](#): heavy tails, dependence, and autocorrelation-consistent standard errors.
- [SIM parameter uncertainty in portfolios](#): rebuild the SIM covariance for each bootstrap draw.
- [Estimation risk in portfolio weights](#): resample the growth data and compare GMV and tangent portfolios on 2025 prices.
- [Data-driven portfolios with a risk-free asset](#): approximate the tangent portfolio from sample estimates.

# Summary

- **Factor models and the single index model:** we introduced factor models, such as the CAPM and the Fama–French model, and kept one market factor to get the SIM. We estimated beta, which measures systematic risk relative to the market, with its uncertainty and fit.
- **Portfolio inputs from a factor model:** we built the covariance from betas and residual variances, with far fewer parameters than a full covariance matrix. The SIM means equal the sample means, so the two portfolios differ mainly through the omitted residual covariances.
- **Risk-free allocation and the tangent portfolio:** we derived the capital allocation line and the tangent portfolio, the risky fund with the largest Sharpe ratio. Lending and borrowing set how much we hold of that fund, and financing limits can change which risky fund we hold.

In L7a and L7b, we turn to utility-based allocation, rebalancing, and updating the SIM parameters as new data arrive.

Next: turn SIM parameters into daily preferences and rebalance the portfolio.
